Abstract

Cultural differences between the US and China have been investigated using a broad array of psychological tasks measuring differences between cognition, language, perception, and reasoning. We examine the robustness of several classic experimental paradigms in cross-cultural psychology. Using online convenience samples of adults, we conducted two large-scale replications of 12 tasks previously reported to show cross-cultural differences. Our results showed a heterogeneous pattern of successes and failures: five tasks yielded robust cultural differences across both experiments, while six showed no difference between cultures, and one showed a small difference in the opposite direction. We observed moderate reliability in all of the multi-trial tasks, but there was little shared variation between tasks. Additionally, we did not see within-culture variation across a range of demographic factors in our samples. Finally, as in prior work, cross-cultural differences in cognition (in those tasks showing differences) were not strongly related to explicit measures of cultural identity and behavior. All of our tasks, data, and analyses are available openly online for reuse by future researchers, providing a foundation for future studies that seek to establish a robust and replicable science of cross-cultural difference.

US-China differences in cognition and perception across 12 tasks: Replicability, robustness, and within-culture variation

Introduction

Cross-cultural differences are a striking part of the broader landscape of human variation. Differences in values and behavior across cultures are obvious to even a casual observer, and researchers have attempted to quantify these differences via a wide range of measures. Comparisons between Western and East Asian cultures have been especially well-researched, with differences attested in a wide range of cognitive domains, including visual attention (Chua, Boland, & Nisbett, 2005; Ji, Peng, & Nisbett, 2000; Waxman et al., 2016), executive function (Sabbagh, Xu, Carlson, Moses, & Lee, 2006; B. Tan, 2020), language learning (Chan et al., 2011, 2011; Tardif, 1996; Waxman et al., 2016), relational reasoning (Carstensen et al., 2019; Cheng, 2020; Richland, Chan, Morrison, & Au, 2010; Su, 2020), similarity judgments (Ji, Zhang, & Nisbett, 2004), values (Ji, Nisbett, & Su, 2001; Kwan, Bond, & Singelis, 1997; Spencer-Rodgers, Williams, Hamilton, Peng, & Wang, 2007), preferences (Corriveau et al., 2017; DiYanni, Corriveau, Kurkul, Nasrini, & Nini, 2015; Liang & He, 2012) and self-concepts (Spencer-Rodgers, Boucher, Mori, Wang, & Peng, 2009; Spencer-Rodgers, Boucher, Peng, & Wang, 2009). As a result, Western and East Asian cultures are increasingly treated as cultural poles in efforts to measure cultural differences (Muthukrishna et al., 2020) and to correct for the pervasive bias in psychology research toward US and European samples (Arnett, 2016; Henrich, Heine, & Norenzayan, 2010; Nielsen, Haun, Kärtner, & Legare, 2017).

Despite a long empirical tradition of comparisons between these cultures and an abundance of psychological accounts for observed differences, estimates of differences are difficult to compare quantitatively because of the varying samples, measures, and methods used in different reports. Further, many of the most prominent reports of cross-cultural differences predate the field-wide discussion of methodological issues in psychology research

during the past 10 years (Open Science Collaboration, 2015). For example, much research in this tradition has been exploratory and hence has not followed current guidance regarding limiting analytic flexibility in order to decrease false positives (Simmons, Nelson, & Simonsohn, 2011). Given the importance of evidence about specific cross-cultural differences for constructing theories of culture more broadly (e.g., Markus & Kitayama, 1992, 2010), further investigation of many empirical findings is likely warranted.

Some empirical evidence points to issues in the robustness of cross-cultural measurements. Typically, measures used in this literature are not standardized and do not have published evidence about reliability and validity (Flake & Fried, 2020). The few extant direct comparisons between measures of cultural difference suggest that theoretically related tasks, such as implicit and explicit measures of the same construct, might not cohere (e.g., Kitayama, Park, Sevincer, Karasawa, & Uskul, 2009). Further, in a study with twenty cross-cultural measures used within a single US sample, Na et al. (2010) found a lack of coherence between tasks measuring social orientation and cognitive style, observing only 8 significant correlations between tasks across 90 statistical tests.[1] Finally, more recent work failed to replicate cultural differences on several related measures (Mercier, Yama, Kawasaki, Adachi, & Van der Henst, 2012; Mercier, Zhang, Qu, Lu, & Van der Henst, 2015; Zhou, Gotch, Zhou, & Liu, 2008). Thus, there is a need to explore the reliability of individual tasks as well as the intercorrelations between them.

Our goal in the current study was to collect a large dataset on a range of cross-cultural measures that had previously been used in comparisons of East Asian and Western cultures, enabling investigations of the robustness of these differences in new samples of Chinese and US participants. We decided to gather relatively large and heterogeneous convenience

---

[1] These authors interpreted their findings as implying that the measures are orthogonal – indexing different constructs – and concluded that group-level differences between cultures are unlikely to relate to within-group individual differences. However, an alternative possibility is that the reliabilities of many individual tasks are low, a feature which would ensure low correlations between them.

samples using online recruitment, rather than recruiting smaller, more matched samples using in-lab recruitment. Our reasoning was that the larger samples that we could access using online recruitment would allow us to conduct highly-powered statistical tests, allowing us to make well-powered tests for cultural differences. Further, larger samples afford the analysis of individual and demographic differences within culture, a topic of considerable interest in this literature (e.g., Na et al., 2010, 2020). Finally, the development of browser-based online versions of prominent cross-cultural tasks would allow their inspection and reuse by other researchers, thus promoting a more cumulative approach to the measurement of cultural differences.

Our experiments were intended to be close replications of the original studies, but differences in format of administration introduced inevitable variation, in some cases more substantial than others. The interpretation of discrepant outcomes between an original study and a replication is complex, given that disparate outcomes can occur for many reasons (Machery, 2020; Nosek & Errington, 2020; Zwaan, Etz, Lucas, & Donnellan, 2018). In our case, interpretation is especially difficult and we explicitly avoid interpreting our results as bearing on the status of the original findings we investigate.

There were some significant differences between our experiments and the original studies. First, we recruited online convenience samples from the U.S. and China. Previous work varied in the participants' country of origin (in several cases, Japan for East Asian participants; Canada for Western participants), largely recruited either college students or community members, and was administered more than a decade ago. Within-culture variation and generational differences between our samples and previous samples make results difficult to compare directly. Furthermore, our strategy of constructing a battery of replication studies and administering them uniformly online altered the contexts in which participants engaged with the tasks and in some cases required alterations to the tasks themselves.

Accordingly, our replication studies should be viewed as an assessment of robustness: specifically, we assess whether a set of previously-reported East-West cross-cultural differences can be recovered in online convenience populations. These are not assessments of the veracity of the original findings. Nevertheless, we believe that cross-cultural psychology can be advanced via the identification of tasks that yield cross-cultural differences robustly across a variety of samples and administration formats – we hope our work contributes to this aim. We return to these interpretive issues in the General Discussion.

Our task selection process was initially shaped by an interest in relational reasoning and accounts explaining it with reference to cross-cultural differences in visual attention and social cognition (Duffy, Toriyama, Itakura, & Kitayama, 2009; Kuwabara & Smith, 2012; Moriguchi, Evans, Hiraki, Itakura, & Lee, 2012). Additionally, in Experiment 1, we selected tasks that could potentially be administered to young children as well as adults, for use in future work addressing developmental questions about the relative time course of cross-cultural differences across the visual, social, and cognitive domains. We balanced three desiderata in our task selection, preferentially choosing tasks that (1) had been theoretically or empirically implicated in relational reasoning, (2) were associated with differential performance in US-China comparisons or related cultural contrasts (i.e., East Asian vs. Western cultures), and (3) were relatively short, accessible tasks appropriate for web administration. We also conducted an extensive set of pilot tests to ensure that participants understood instructions and that the tasks yielded interpretable data.

In Experiment 2, we selected a second set of tasks to investigate based in part on the results of Experiment 1. In particular, we repeated a handful of tasks from Experiment 1, in some cases, varying task parameters. We then selected a further set of tasks that probed both cross-cultural differences in higher-level cognition (e.g., language and reasoning) and perception, again respecting the desideratum that the tasks should be relatively short and amenable to administration in a web browser. The final set of tasks included in each

experiment is listed in Table 1.

In addition to the goal of replicating individual tasks, our hope was that the relatively large dataset we collected could be used to explore the structure of within- and between-culture variation in cognition and perception more broadly. Towards this goal, we included a relatively extensive demographic questionnaire in both of our experiments, with the aim of using these measures to explore variation within our samples. In the final section of the paper, we report a series of exploratory analyses. The first of these assesses the reliability of individual tasks to gauge whether these tasks are reliable enough from a psychometric point of view to support further individual differences analyses. We then report correlations across tasks, aiming to discover covariation between tasks that might indicate that they load on the same construct. Finally, we turn to analyses of whether within-culture demographic variables predict variation in task performance. Overall, a number of tasks revealed acceptable levels of reliability, but tasks did not cluster together, and we found relatively few demographic predictors of within-culture variation.

We make all code and data from our experiments available for further data collection and analysis in hopes of promoting further cumulative work on measures and theories of cross-cultural variation.

Table 1
Tasks included in each experiment and the final sample size after exclusions. We conducted simulations for power analysis and found that our sample sizes are well-powered to detect medium and above effect sizes. We included the power analyses in Appendix A.

Experiment 1

In Experiment 1, our goal was to evaluate cross-cultural differences in a variety of constructs. We assembled a web-based battery of tasks and tested these on a snowball sample of US and Chinese participants.

Methods

Participants. We recruited participants through snowball sampling seeded at large universities in the US and China, in which participants directly recruited by the researchers were encouraged to recruit their friends and family members through email forwarding and social media sharing. Participants in the US were compensated with $5 gift certificates (USD) and participants in China received ¥35 (CNY).

We recruited 203 and 201 participants each from the US and China, respectively. Since we did not have strong a priori expectations about specific effect sizes, our overall preregistered sample size was chosen to meet or exceed the sample sizes used in prior reports

167 in the literature from which our tasks were drawn. Our sample size, methods, and main

168 analyses were pre-registered and are available at https:// aspredicted.org/37y6a.pdf.

169   Our preregistered exclusion plan was to exclude people from the full dataset if they

170 failed quality checks[2] on any one task, unless this excluded 20% or more of our sample. Due

171 to a task demand associated with the Symbolic Self-Inflation task, this criterion would have

172 led to the exclusion of 107 people (US: 66, CN: 41) due to this task alone. This triggered the

173 less restrictive exclusion approach in our preregistration, using task-specific quality checks to

174 exclude participants only from the relevant individual task.

175   After exclusions, the US sample included 180 participants (49 Male, 120 Female, 9

176 Non-binary, 2 Declined to answer), with a mean age of 22.02 years old, all of whom were

177 native English speakers. The China sample included 191 participants (60 Male, 127 Female,

178 1 Non-binary, 3 Declined to answer), with a mean age of 22.42 years old, who were all native

179 speakers of Mandarin Chinese. This sample size is shared among all tasks except for the

180 Symbolic Self-Inflation task, which included 114 US participants and 150 CN participants.

181   In addition to age, gender, and linguistic background, we collected a range of

182 demographic information including subjective socioeconomic status measured using the

183 MacArthur Ladder (Adler, Epel, Castellazzo, & Ickovics, 2000), level of maternal education,

184 the state or province the participant grew up in, residential mobility, and number of

---

[2] We performed exclusion based on three aspects: side bias, missing data, and demographic exclusions.
(1) Side bias: If more than 90% of selections by a participant in a 2AFC task were a single response button (left or right), data from this participant in this task would be excluded.
(2) Missing data: If no data/more than 25% missing/data not codeable/side bias/participant did not follow instructions for any one task, then we would exclude all data from that participant, across tasks. If this led to 20% or more of participants being excluded, we would not apply this exclusion criteria to all data from the participant – only at the level of individual tasks.
(3) Demographic exclusions: We would exclude data from [CN/US] participants who reported living abroad for more than 2 years in regions with predominantly [European/Asian] populations (respectively); and [CN/US] participants who reported speaking or understanding [English/any Chinese language or dialect] with proficiency at or above 3 out of 10. If this led to 20% or more of participants being excluded from either test population (US/CN), we would drop this exclusion criterion for the relevant population and use exploratory regressions to examine how the factor relates to responding in our tasks.

international experiences.

Procedure. Participants completed an online, browser-based sequence of eight tasks (see Table 1) and a brief demographic questionnaire. All tasks were implemented in a combination of jsPsych (De Leeuw, 2015) and custom HTML/JavaScript code. Tasks were administered in English for the US sample and in Mandarin Chinese for the China sample. To control for the impact of order-related inattention, task order was randomized across participants with two exceptions: (1) the two drawing tasks (Symbolic Self-Inflation and Horizon Collage) were always back-to-back in random order, and (2) Uniqueness Preference was always the penultimate task (in keeping with the task cover story, which congratulated participants on being nearly done with the experiment). In total, the experiment took about 30 minutes to complete.

Measures. Below, we give a short description of prior findings and methods for each task.

Ambiguous cRMTS. Carstensen et al. (2019) observed cross-culturally distinct developmental trajectories in a causal relational match-to-sample (cRMTS) task, and different preferences in an ambiguous formulation of this task. Specifically, when 3-year-olds saw evidence consistent with both object-based (e.g., blue cubes make a machine play music) and relational (pairs of different objects, AB, make a machine play music) solutions, children in the US sample preferentially chose the object-based solution, while those in China chose the relational solution.

We used this ambiguous version of the task (Carstensen et al., 2019, Experiment 3) to explore whether adults in the US and China also show differing preferences for object-based or relational solutions. Our participants saw two pairs of objects, AB and AC, activate a machine, and were given a forced choice between an object-based solution (a *same* pair of A objects, AA) and a relational solution (*different* pair BC).

Picture Free Description. Imada, Carlson, and Itakura (2013) found that children around the age of 6 showed cultural differences in describing pictures to others.

Relative to US children, Japanese children were more likely to mention the objects in the background first, as opposed to the focal objects in the picture. They also tended to provide more descriptive accounts of the background objects than their US counterparts. In our version of the task, we used a subset of seven images from the original study and adapted the task for adult participants, who studied each image for 5 seconds and then typed a description. We coded the first mentioned item (focal or background) and counted descriptors for focal and background elements.

Ebbinghaus Illusion. Both Japanese adults and children have been found to be more susceptible to the Ebbinghaus Illusion – in which context alters the perceived size of a circle – than Western participants in the US and UK (Doherty, Tsuji, & Phillips, 2008; Imada et al., 2013). We followed the Imada et al. (2013) implementation of the task, with two testing blocks: the No Context block (10 trials) and Illusion block (24 trials). The No Context block establishes baseline accuracy for discriminating which of two orange circles is larger. In the Illusion trials, the two orange circles are flanked by a grid of 8 gray circles, which are all smaller or larger than the center orange circle. The illusion occurs because the orange circles appear larger when flanked by smaller gray circles, leading to distortions in comparing the sizes of the two orange circles with differing contexts (i.e., small or large flankers). Across the 24 Illusion trials, we measured accuracy of circle size judgments as a function of the actual size difference and flanker context (helpful or misleading).

Horizon Collage. Senzaki, Masuda, and Nand (2014) found that school-age children in Japan and Canada showed culture-specific patterns when creating a collage of an outdoor scene. Japanese children drew the horizon higher, used more collage items, and filled more space with collage items relative to Canadian children. We adapted the task from Senzaki et al. (2014) Study 2, in which participants were prompted to make a collage with stickers. Our participants could drag any of thirty images (line drawings of people, animals, houses, etc.) onto a rectangular "canvas" in the middle of the screen. There was also a sticker "horizon," a horizontal line that spanned the length of the canvas. All stickers,

including the horizon, could be clicked and dragged to the canvas to produce "a picture of the outside." Participants were asked to include a horizon and any number of other stickers to create their image. We measured the height of the horizon, the number of stickers used, and the total area occupied by stickers as in Senzaki et al. (2014).

   Symbolic Self-Inflation.   Kitayama et al. (2009) found a difference between Western and East Asian cultures in the size of circles participants drew to represent themselves relative to other people in their social networks. Japanese participants drew circles of similar sizes to represent themselves and others, while those from Western countries (US, UK, Germany) tended to draw their "self" circles larger than those representing others, indicating a symbolic self-inflation in the three western cultures compared to Japan. We adapted this task, asking participants to draw themselves and the family members they grew up with as circles by clicking and dragging the mouse on a rectangular "canvas" to draw circles of varying sizes. They then labeled each circle for the person it represented. We measured the diameter of each circle and calculated a percent inflation score for each participant by dividing the diameter of the self circle by the average diameter of circles for all others.

   Uniqueness Preference.   Kim and Markus (1999) tested East Asians' and Americans' preferences for harmony or uniqueness by asking them to pick one gift pen from five options. In the condition that we replicated, the options differed only in the barrel colors, with four that were the same and one that was unique. They found that European Americans were more likely to choose the unique colored pen than East Asian participants. We adapted our task to better fit the format of our online experiment by showing a virtual "sticker book" to measure progress through all tasks in our study. At the end of each task, participants received a virtual sticker. For the uniqueness preference task, we let them select one of five dinosaur stickers that were identical except for color: four blue and one yellow (with repeated and unique colors randomized between participants). Choice of the unique vs. repeated color was recorded.

266   ***Child Causal Attribution.***   Previous work has shown that participants from South

267   Korea and the U.S. attribute behaviors differently in situations where there is evidence in

268   favor of situational explanations (Choi, Nisbett, & Norenzayan, 1999). Similarly, Chinese

269   participants and media are more likely than their US counterparts to attribute a person's

270   behaviors to situational context as opposed to individual traits (Morris, Nisbett, & Peng,

271   1995; Morris & Peng, 1994). We adapted the deterministic situation condition in Seiver,

272   Gopnik, and Goodman (2013), a task originally designed for children. In this task, two

273   children both engage in one activity and avoid another, suggesting that situational

274   constraints (e.g., the latter activity being dangerous) may be guiding their decisions.

275   Participants watched a series of four short, animated vignettes in which two children both

276   played in a pool and neither child played on a bicycle. We then asked participants to explain

277   in text why each child did not play on the bicycle, making for two test trials per participant.

278   We used the prompt question from Seiver et al. (2013), which explicitly pits person

279   attributions against situational ones: "Why didn't Sally play on the bicycle? Is it because

280   she's the kind of person who gets scared, or because the bicycle is dangerous to play on?"

281   We coded each response for per-trial count of (a) personal and (b) situational attributions.

282   ***Raven's Standard Progressive Matrices.***   As an additional attention check as

283   well as an exploratory measure of relational reasoning assessing performance rather than

284   preference, we included the 12 questions from Set E of Raven's Standard Progressive

285   Matrices. Su (2020) found cross-cultural differences between adults in the US and China in

286   performance on this set. This set of questions was selected because it is the most difficult

287   subset and also the one most dependent on true analogical reasoning, without alternative

288   heuristic approaches like visual pattern completion.

289   **Analyitic approach.**   Data and analysis scripts are available at

290   https://github.com/anjiecao/CCRR_writeups

291   The papers that we drew on for our tasks used a heterogeneous set of analytic methods.

292   Rather than planning to replicate these specific analyses, we instead attempted to follow

current best practices by using linear mixed effects models with maximal random effect structure as a unified analytic framework (Barr, Levy, Scheepers, & Tily, 2013). We fit a separate model to each task. In case of convergence failure, we followed lab standard operating procedures: pruning random slopes first and then random intercepts, always maintaining random intercepts by participant. For linear models, we report p-values derived from t-scores. For linear mixed models, we report p-values derived from z-scores, which is appropriate for relatively large samples (Blouin & Riopelle, 2004). Our key tests of interest were typically either the coefficient for a main effect of country (US/China) or an interaction of country and condition.

Discussion

We did not observe cross-cultural differences in the majority of tasks in Experiment 1. The only exceptions were in Picture Free Description and our exploratory measure of performance in relational reasoning (Raven's SPM). We also found cultural difference in the opposite direction in one of the measures in the Horizon Collage task. Many of our tasks did not have a manipulation check and could yield null results simply by virtue of inattention. However, the results of Raven's SPM (and the Ebbinghaus Illusion) suggest that participants were engaged in our tasks and performed at a high objective level. In addition to minor methodological changes that we made, interpretation of our failure to replicate individual tasks in many cases could be due to (1) differences in administration (online vs. in-person), (2) differences in participant recruitment (e.g., university pool vs. snowball sampling), (3) differences in target age (adults vs. children), and (4) differences in sample (e.g. Japanese vs. Chinese adults in the East Asian group).

Our failure to find robust differences between Western and East Asian cultures in this

initial selection of tasks was dispiriting. We designed Experiment 2 to extend Experiment 1 by recruiting a different sample and identifying followup or replacement tasks that we hoped would yield a broader set of cross-cultural differences.

Experiment 2

Experiment 2 was designed to follow up on Experiment 1 and further evaluate cross-cultural differences across a battery of tasks. Because several of our tasks in Experiment 1 yielded no evidence for cross-cultural differences, we replaced these with alternative tasks selected to address similar or related constructs. We replaced the Ebbinghaus Illusion with a measure of Change Detection that has been argued to index context sensitivity (Masuda & Nisbett, 2006). We replaced the child-appropriate causal attribution task with a version designed for adults (Morris & Peng, 1994). We also included two tasks measuring linguistic or semantic intuitions more broadly (Taxonomic/Thematic Similarity and Semantic Intuition), following up on the detection of cross-cultural differences in the Picture Free Description task. Although our goal in Experiment 2 was to evaluate a further set of tasks, we also included the Ambiguous cRMTS, Picture Free Description, and Raven's Progressive Matrices tasks to replicate our results from Experiment 1, and we included a modified version of Symbolic Self-Inflation to address several issues with the earlier version of the task.

In Experiment 2, we made use of crowd-sourcing services – rather than snowball sampling – as our participant recruitment channel. We had two rationales. First, in Experiment 1 our samples were quite young (due to seeding our sampling with university students through email and social media). A younger sample may be less enculturated because they are less experienced or more exposed to international media and influences, and thus less likely to show distinct cross-cultural differences. Second, we were concerned that being recruited by friends and family (as in a snowball sample) might prime interdependent thinking among our participants, leading to decreased cross-cultural differences.

Methods

Participants.   We recruited participants through online crowdsourcing websites. For the US, we used Prolific and applied the following screening criteria: a) US nationality, b) born in the US, and c) currently residing in the US; For China, we used Naodao (www.naodao.com), a platform designed for conducting online experiments in mainland China. Participants in US received $12.25 in compensation and in China ¥35.

We recruited 304 participants from the U.S. and 185 participants from China. 10 participants were excluded because they did not meet our demographic inclusion criteria[3]. Following our preregistration (available at https://osf.io/u7mzg), we applied a task-based exclusion procedure in which we excluded a participant's responses in a particular task if they a) showed a response bias for a single response button or value[4], b) had missing data on more than 25% of trials[5], or c) failed to meet the inclusion criteria for that task as specified in the preregistration[6].

---

[3] Demographic exclusions: we would exclude data from [CN/US] participants who reported living abroad for more than 2 years in regions with predominantly [European/Asian] populations (respectively); and [CN/US] participants who reported speaking or understanding [English/any Chinese language or dialect] with proficiency at or above 3 out of 10. If this led to 20% or more of participants being excluded from either test population (US/CN), we would drop this exclusion criterion for the relevant population and use exploratory regressions to examine how the factor relates to responding in our tasks.

[4] If more than 90% of selections by a participant in a 2AFC task were a single response button (left/right in RMTS or top/bottom in taxonomic/thematic similarity), data from this participant in this task would be excluded. If 100% of selections by a participant in a scalar (e.g., Likert scale used in causal attribution or in the demographics section) or multiple choice task (e.g. Raven's SPM) used a single response button/value, data from this participant in this task would be excluded.

[5] If no data/more than 25% missing/data not codeable/side bias/participant did not follow instructions for any one task, then we would exclude all data from that participant, across tasks. If this led to 20% or more of participants being excluded, we would not apply this exclusion criteria to all data from the participant – only at the level of individual tasks.

[6] Additional task and trial-level exclusions:
(1) Change detection: trials where the participant incorrectly identified the change would not be analyzed (but will not be counted as missing data unless a response was not attempted).
(2) Free description: trials where the response was not code-able would be discarded and considered missing data.
(3) Causal attribution: none.
(4) Symbolic self-inflation: data from participants who failed to draw exactly one "self" circle would be excluded, as well as data from participants who drew only a "self" circle.
(5) Taxonomic/thematic similarity task: There were two unambiguous catch trials intermixed with regular

Similar to Experiment 1, we collected demographic information from participants, including subjective socioeconomic status, the state or province the participant grew up in and the one they currently reside in, residential mobility, number of international experiences, education, and undergraduate area of study (STEM or non-STEM). We also administered scales to collect explicit measures of participants' cultural identities and behaviors (Cleveland & Laroche, 2007; Cleveland, Laroche, & Takahashi, 2015).

The sample size for each task after exclusions and the descriptive statistics for each demographic question are reported in Table 1.

Procedure.   Similar to Experiment 1, participants completed eight tasks and a brief demographics questionnaire online. The experiment was administered in English for the US sample and in Mandarin Chinese for the Chinese sample, with the exception of the Adult Causal Attribution task. As in previous work, this task was administered in English, and only Chinese participants who self-identified as being able to read English participated in it. To control for the impact of order-related inattention, task order was randomized across participants with two exceptions: (1) the Free Description task always occurred before (not necessarily immediately) Change Detection (because Change Detection included a manipulation check that explicitly asked about focal objects, which could bias responding in Free Description), and (2) the two story-based tasks (Semantic Intuition and Adult Causal Attribution) always occurred together in a fixed order at the end of the study, with Semantic Intuition first and Adult Causal Attribution last. Adult Causal Attribution was always the last task (if run) because it was administered in English and we did not wish to prime CN participants with English stimuli before any of the other tasks, all of which were run in Mandarin.

Measures.

---

trials in this task (e.g., Choose cat: cat, dog). If a participant missed either unambiguous catch trial, all triad data from that participant would be excluded.
(6) Semantic intuition: Participants would be excluded for missing any of the 5 control questions.
(7) Ambiguous RMTS: none.
(8) Raven's SPM: none.

381 ***Tasks from Experiment 1.*** We replicated three tasks from Experiment 1 using

382 identical procedures: Ambiguous cRMTS, Picture Free Description, and Raven's Standard

383 Progressive Matrices.

384 ***Symbolic Self-Inflation.*** Participants were asked to draw themselves and their

385 friends as circles, as opposed to drawing themselves and their family members as circles in

386 Experiment 1. They were also asked to draw lines between any two people who are friends,

387 as in the original study by Kitayama et al. (2009). They then labeled each circle to indicate

388 the person it represents. We calculated a percent inflation score for each participant by

389 dividing the diameter of the self circle by the average diameter of circles for others.

390 ***Adult Causal Attribution.*** We speculated that the lack of cross-cultural

391 differences in Causal Attribution in Experiment 1 might be due to the simplistic nature of

392 our task, which was designed for use with young children. Therefore, in Experiment 2 we

393 used a paradigm designed for adults, in which participants were asked to read a crime

394 narrative from a news report that included substantial information on a criminal's

395 background and the events leading up to their crime, and then rate the relevance of various

396 situational and personal factors (Morris & Peng, 1994). In the original study, both Chinese

397 participants and US participants read stories in English. We followed this procedure by

398 selecting the subset of our Chinese participants who self-identified as comfortable reading

399 short stories in English to participate. In the task, participants were told that they would

400 read news stories and answer questions to help social scientists understand the factors that

401 contribute to murders. Participants were randomly assigned to read one of two stories (Iowa

402 shooting or Royal Oak shooting). After the stories, they were asked to write a short

403 explanation for the murderer's behaviors. Then, they rated a list of statements about causes

404 of the murder on a 7-point Likert scale. The statements included items that describe

405 personal and situational factors, and we measured endorsement of these two factor types.

406 ***Change Detection.*** Masuda and Nisbett (2006) found differences in attention

407 allocation between Japanese and US participants in a change detection paradigm. They

found that Japanese participants were significantly faster than US participants in identifying

changes in the background of images. We followed their original procedure and used the

same stimuli. In this task, participants were presented with 30 pairs of images. On each trial,

two pictures would alternate on the screen, each presented for 560ms with a blank screen in

between images for 80ms. The two pictures were almost identical with subtle differences,

either in the focal object (e.g., a tractor in daylight with its lights on or off) or the

background (e.g., a cloud with slightly different locations in the sky). Participants were

instructed to press a key when they spotted the difference, and then describe the difference

in a text box. If they did not detect a difference within 60 seconds, the trial timed out. Only

trials in which participants correctly identified the changes were included in the analysis.

After 30 trials, participants saw each pair of images again, this time side-by-side on the

screen. They were asked to identify the focal object(s) in the pictures by typing into a text

box. These responses were used as a manipulation check to ensure that participants in both

cultures construed focal objects similarly.

We coded change descriptions to exclude trials in which participants did not identify

the change, and checked agreement on focal objects across cultures. We measured how

quickly participants identified the difference on trials in which they reported the difference

correctly.

Taxonomic-Thematic Similarity.   Ji et al. (2004) showed that Chinese

participants are more likely to match items based on thematic similarity, whereas US

participants are more likely to match items based on taxonomic similarity. In this task,

participants were presented with triads containing a cue word and two match options. In

each test set, one option was a taxonomic match (e.g., monkey - elephant) and the other a

thematic match (e.g., monkey - banana). In each filler set, the cue item and the options were

broadly similar, thematically and taxonomically, making for a more ambiguous decision (e.g.,

monkey: elephant, tiger). Participants completed a two-alternative forced choice task in

which they chose one match for each cue item.

435   The findings of Ji et al. (2004) were replicated in more recent work (Le, Frank, &

436 Carstensen, 2021); we used a subset of testing materials from Le et al. (2021), with 15 test

437 triads, 15 filler triads, and 2 attention check questions. The order of the triads was

438 randomized between subjects. We measured taxonomic vs. thematic match selections on

439 each of the test trials.

440   ***Semantic Intuition.***   Li, Liu, Chalmers, and Snedeker (2018) found cultural

441 differences in semantic intuitions about ambiguous referents in Chinese and US participants.

442 Specifically, Chinese participants were more likely to determine the referent of a name based

443 on the description of the speaker (the descriptivist view) whereas US participants were more

444 likely to determine the referent based on the original usage (the causal-historical view). In

445 the study, participants read five separate stories and judged the correctness of statements

446 referring to a character after each story. Two comprehension check questions were included

447 for each story. We followed the original procedure closely and used the same materials. We

448 measured participants' semantic intuition as their judgment on the correctness of statements

449 referring to the critical characters.

450 **Results**

451   **Ambiguous cRMTS.**   Our analysis was identical to that in Experiment 1. We did

452 not observe a main effect of country on participants' preference for object vs relational

453 matches (proportion relational match: US: $M = 0.41$, $SD = 0.44$; CN: $M = 0.41$, $SD = 0.42$;

454 $\beta = -0.01$, $SE = 0.48$, $z = -0.03$, $p = 0.98$). As in Experiment 1, we did not find evidence

455 that the differential preferences observed in preschoolers extend to adults. It seems likely

456 that adults in both populations are aware of the mixed evidence for the relational and object

457 solution and that their responses reflect sensitivity to this ambiguous design.[7]

---

[7] Our reliability analysis shows that adults expressed this uncertainty only at the population level: individuals tended to be consistent in choosing the same solution type across all four test trials, with ambiguity expressed as disagreement between participants.

458   **Picture Free Description.**   US participants were more likely to initially mention

459 the focal objects than the background objects (first mention: US: $M = 0.94$, $SD = 0.14$; CN:

460 $M = 0.69$, $SD = 0.26$). We used the same regression analysis as in Experiment 1 and found

461 a main effect of country ($\beta = 3.09$, $SE = 0.32$, $z = 9.61$, $p < 0.01$). Our results replicate the

462 first mention finding in Experiment 1 with a comparable effect size (standardized mean

463 difference; Experiment 1: 1.50[1.26, 1.74]; Experiment 2: 1.57[1.34, 1.80]).

464   We also deviated from our pre-registered analysis plan and coded for the number of

465 descriptive accounts directed at the focal objects and background objects using the same

466 coding schemes as Experiment 1. We ran the same mixed-effect Poisson regression model

467 predicting the number of descriptive accounts, with the interactions between description type

468 (focal or background) and country (U.S. or China) as the predictor. Interestingly, we did not

469 replicate the results in Experiment 1, but found patterns similar to the results in Imada et al.

470 (2013). We found an interaction between country and type of description ($\beta = 0.16$, $SE =$

471 0.07, $z = 2.24$, $p < 0.05$). Chinese participants, in contrast to U.S. participants, provided

472 more descriptive accounts of the background objects relative to the focal objects (for focal

473 objects: US: $M = 0.66$, $SD = 0.82$; CN: $M = 0.50$, $SD = 0.64$; for background objects: US:

474 $M = 0.69$, $SD = 1.07$; CN: $M = 0.61$, $SD = 0.80$).

475   In summary, these results extend Imada et al.'s (2013) findings to Chinese adults.

476   **Change Detection.**   We ran a linear mixed-effects model predicting the reaction

477 time to correctly identified changes in the pictures, with country (U.S. or China) and type of

478 change detected (focal or background) as main effects, as well as their interaction. We did

479 not find evidence for an interaction between culture and type of change detected ($\beta = 0.04$,

480 $SE = 0.03$, $z = 1.40$, $p = 0.16$). Participants in both countries identified changes to the

481 context faster than changes to focal objects (context changes: $M = 10{,}101.87$, $SD =$

482 $4{,}257.15$; focal object changes: $M = 10{,}646.54$, $SD = 4{,}816.10$; $\beta = 0.07$, $SE = 0.02$, $t =$

483 3.45, $p < 0.01$). Chinese participants identified both types of change more quickly than US

participants (US: $M = 10,689.49$, $SD = 4,406.73$; CN: $M = 9,875.67$, $SD = 4,733.57$; $\beta = 0.12$, $SE = 0.05$, $t = 2.27$, $p < 0.05$).

As an exploratory analysis, we also retroactively analyzed the coded accuracy of the participants' responses. Interestingly, we found main effects of culture and the type of change, as well as an interaction between culture and the type of change. Participants across both countries were more accurate in identifying changes of the focal objects than the context objects, and Chinese participants were more accurate in identifying the changes than the U.S. participants on average (US focal: $M = 0.90$, $SD = 0.30$; US context: $M = 0.85$, $SD = 0.36$; CN focal: $M = 0.94$, $SD = 0.24$; CN context: $M = 0.89$, $SD = 0.32$). However, the difference between Chinese participants and U.S. participants was larger in focal changes than in background changes, with Chinese participants being more accurate than U.S. participants in the focal changes than in the context changes ($\beta = -0.22$, $SE = 0.09$, $z = -2.53$, $p < 0.05$). This interaction is different from our predictions: If we extrapolate from the original study, we should expect to see a difference in the background context, with participants performing similarly in the background changes but Chinese participants being more accurate in the background changes than U.S. participants.

In sum, we did not replicate the findings of Masuda and Nisbett (2006).

Symbolic Self-Inflation.   In Experiment 1, we did not find a significant difference in the degree of symbolic self-inflation between adults in the US and China. Here, we observed a pattern contrary to the prediction: US adults showed less self-inflation than Chinese adults (US: $M = 1.30$, $SD = 0.51$; CN: $M = 1.45$, $SD = 0.65$; $\beta = -0.15$, $SE = 0.06$, $t = -2.56$, $p < 0.05$). We did not replicate the findings of Kitayama et al. (2009) with Japanese participants in either of our experiments.

Adult Causal Attribution.   We ran a mixed-effects linear regression predicting endorsement of each potential cause with country (US or China) and attribution type (personal or situational) as fixed effects, as well as their interaction. We found an interaction

in the predicted direction: Chinese participants endorsed situational attributions to a greater extent than their counterparts in the US (situational ratings: US: $M = 1.71$, $SD = 0.80$; CN: $M = 3.17$, $SD = 0.89$; personal ratings: US: $M = 3.12$, $SD = 1.10$; CN: $M = 3.14$, $SD = 1.07$; $\beta = -1.39$, $SE = 0.14$, $t = -9.71$, $p < 0.01$). This result extends the original findings by Morris and Peng (1994), and suggests that the measure of causal attribution in Experiment 1 (which was designed for use with child participants) may not be appropriate for measuring cross-cultural differences in causal attribution among adults.

Taxonomic-Thematic Similarity. We used a mixed-effects logistic regression predicting response (taxonomic or thematic match) with country (US or China) as a fixed effect. There was a significant effect in the predicted direction: participants in the US were more likely to choose taxonomic matches than participants in China (proportion taxonomic matches: US: $M = $ NA; $SD = $ NA; CN: $M = $ NA; $SD = $ NA; $\beta = 2.02$, $SE = 0.89$, $t = 2.27$, $p < 0.05$). This finding replicates the findings of Ji et al. (2004) and Le et al. (2021).

Semantic Intuition. We ran a mixed-effects logistic regression predicting response (descriptive or causal-historical) with country (US or China) as a fixed effect, and found that US participants made significantly more causal-historical choices than Chinese participants (proportion causal historical choice: US: $M = 0$; $SD = 0$; CN: $M = 0$; $SD = 0$; $\beta = 1.59$, $SE = 0.37$, $t = 4.37$, $p < 0.01$). We also replicated the item effect identified by Li et al. (2018), though this was not among our preregistered analyses. In sum, We replicated Li et al. (2018) with new samples of adults in the US and China.

Raven's Standard Progressive Matrices. We replicated the findings from Experiment 1. Chinese participants scored higher on Raven's Standard Progressive Matrices than US participants (US: $M = 0.49$, $SD = 0.27$; CN: $M = 0.73$, $SD = 0.23$; $\beta = -1.82$, $SE = 0.25$, $z = -7.39$, $p < 0.01$).

Discussion

Overall, Experiment 2 was more successful than Experiment 1 in documenting cross-cultural differences between participants in the US and China. This success can be attributed to the inclusion of the successful tasks from Experiment 1 (e.g., Free Description and Raven's Standard Progressive Matrices), and the exclusion of tasks designed for young children (e.g., Child Causal Attribution, Horizon Collage).

Exploratory analyses

We conducted a set of exploratory analyses to consolidate results from the two experiments. We first performed a miniature meta-analysis with the tasks from both experiments. Then, we assessed the reliability of the tasks that included multiple trials, the relationships between tasks, and finally, how explicit cultural identities and demographic factors relate to task performance.

Mini meta-analysis

As our first exploratory analysis, we identified the key effect of interest from our pre-registration (usually a main effect of culture or an interaction of culture, depending on task) and converted the coefficient into a standardized measure of effect size (standardized mean difference; SMD) via the method described by Westfall, Kenny, and Judd (2014). Because there is no "correct" direction for any task except Raven's SPM, we show the absolute value of the effect sizes (Figure 1).

Across our two experiments, we saw consistent and generally large differences (SMD > 0.6) in Free Description, Raven's SPM, Adult Causal Attribution, Semantic Intuition, and Taxonomic-Thematic Similarity tasks. Aside from Raven's SPM, all of these tasks have in common that they are deliberative linguistic tasks that tapped into relatively high-level cognitive constructs. In contrast, we observed effect sizes close to zero for our more aesthetic and perceptual tasks (Change Detection, Ebbinghaus Illusion, and Horizon Collage). We
Figure 1. Forest plot of effect sizes (standardized mean difference) for each task across both experiments. Point shape shows experiment number and color indicates whether effects were consistent with prior literature.

also observed little consistent difference in four other tasks (Ambiguous cRMTS, Symbolic Self-Inflation, Uniqueness Preference, and Child Causal Attribution), perhaps for reasons idiosyncratic to each. We return to the broader question of generalization across task types in the General Discussion.

We conducted three additional exploratory analyses to consolidate results from the two experiments. First, we assessed the reliability of the tasks that included multiple trials. Second, we examined whether there was shared variance between tasks. Finally, we examined how explicit cultural identities and demographic factors relate to task performance.
Figure 2. Spearman-Brown adjusted reliabilities for tasks with four or more trials. Point shape shows experiment number. Error bars show 95% confidence intervals.

Reliability assessment

One question motivating our work was whether the individual tasks we used were reliable enough – had low enough measurement error – to be used for further investigation of individual differences. The gold standard for evaluating whether a task yields stable within-person measurements is test-retest reliability (simply because test-retest gives a direct estimate of stability over time), but this method was outside the scope of our study. Instead, we used a split-half approach, asking whether participants' answers on individual questions relate to one another. Specifically, we used a permutation-based split half approach (Parsons, 2021) in which we made 5000 random splits of items into two simulated "halves" and then computed the within-person correlation between scores on these two halves, averaging across simulated runs. To estimate the reliability of the full-length instrument, we used the

578 Spearman-Brown "prophecy" formula.

579   Since the split-half approach is only suitable for tasks with multiple trials, we removed

580 tasks with fewer than four trials from the analysis. For tasks with more than one condition,

581 we focused on the condition that was predicted to show cultural differences (i.e., the Illusion

582 context in the Ebbinghaus Illusion; situational factors in Adult Causal Attribution;

583 background change scenes in Change Detection).

584   Figure 2 shows the corrected split-half reliabilities for all tasks in both of our

585 experiments. Overall, the reliabilities were acceptable (all Spearman-Brown Correlations >

586 0.6). We further investigated whether there was cultural variation in the reliability of tasks.

587 For most tasks, the reliabilities were relatively similar (within 0.1 of one another), but there

588 were three tasks where reliability was lower for US participants than Chinese participants:

589 Change Detection (US - CN = -0.19), Adult Causal Attribution (US - CN = -0.33), Free

590 Description in Experiment 1 (US - CN = -0.23).

591 **Relations between individual tasks**

592   One (perhaps simplistic) interpretation of the prior literature on cultural variation is

593 that there is a general tendency toward holistic or analytic reasoning that varies across

594 cultures and explains variation in tasks. This single dimension might correspond to broad (or

595 focused) attention and contextualized, relational reasoning (or an emphasis on focal people

596 or objects). As a first step towards investigating this interpretation, we explored whether

597 there was a single dimension of individual variation in our data that corresponded to this

598 general axis of cross-cultural difference. Because some data was missing, largely due to

599 task-related exclusions, we treated the missing data using two approaches: listwise deletion

600 and imputation with means. These approaches yielded comparable results, so here we report

601 correlations from listwise deletion.

602   Correlations between task scores were quite low on average, suggesting limited support

603 for a single factor explanation. Across both experiments, the largest absolute magnitude of

604 correlations observed were -0.29 (Taxonomic-Thematic Similarity and Adult Causal

605 Attribution in Experiment 2), -0.28 (Free Description and Raven's SPM in Experiment 2),

606 and -0.24 (Adult Causal Attribution and Free Description in Experiment 2). All other

607 correlations were between -0.23 and 0.23. Hence, the amount of shared variation between

608 tasks was quite limited and our attempts at exploratory factor analysis discovered structures

609 with many distinct factors and very low loading on the first factor.

610 We also applied the same correlation analysis within each culture. Again, we found

611 limited correlations between tasks. This pattern replicated the findings from a previous work

612 showing negligible relationships among a battery of tasks that revealed cultural differences

613 (Na et al., 2010) (See Appendix C).

Demographic variation and explicit measures of cultural identity

615 As a final exploratory analysis, we asked whether demographic variation or variation in

616 cultural identity predicted responding in our tasks. Our approach to these questions was to

617 fit a set of exploratory regression models for each task, predicting task scores as a function of

618 an individual scale and its interaction with culture. This approach allowed us to explore

619 both within- and between-culture effects in a single model. Our predictors were 1) the

620 summed score for our global/local cultural identity and consumption measures (with local

621 items reverse-scored, such that higher scores represent more global identities and

622 consumption patterns); 2) geographic information about where participants grew up Markus

623 & Conner (2014); and 3) a range of demographic factors, including age, gender identity,

624 residential mobility, number of international experiences, maternal education level, and

625 subjective socioeconomic status as measured by the MacArthur Ladder (Adler et al., 2000).

626 **Task performance and global identity.** We fit models predicting task

627 performance based on culture and its interaction with global (vs local) identity for tasks in

628 Experiment 2 (we did not collect these scales in Experiment 1). Two of these relationships

were statistically significant at $.01 < p < .05$ (Adult Causal Attribution: $p = 0.05$;

Taxonomic-Thematic Similarity: $p = 0.04$) but neither of these relationships survived

Bonferroni correction for multiple comparisons.

Task performance and geographic origin.   We next considered whether regions

within each country were meaningful predictors of task performance. We fit models

predicting task performance based on the regions that participants reported growing up in.

For China, provinces were categorized as rice-cultivating regions or wheat-cultivating regions

based on Talhelm et al. (2014). For the US, states were categorized based on either the

coastal locations (West Coast, East Coast, and Inland) or broad geographic locations (West,

South, Northeast, Midwest), following the categorization reported in Carstensen, Saponaro,

Frank, and Walker (2022).

5 out of the 48 models we ran showed statistically significant relationships between

regions and task performance. In Experiment 1, US coastal location was a significant

predictor for the Free Description task. Participants who grew up in Inland regions ($N = 54$)

or on the East Coast ($N = 27$) were more likely to mention the focal object first when

describing the pictures than participants who grew up on the West Coast ($N = 84$; Inland: p

$= 0.02$; East Coast: $p = 0.05$). In Experiment 2, both coastal location and broad geographic

location were significant predictors for Raven's SPM, with participants from the East Coast

($N = 89$) and Inland regions ($N = 159$) scoring higher than participants from the West

Coast ($N = 46$; Inland: $p < 0.01$; East Coast: $p = 0.05$), and participants from the Midwest

($N = 78$) and South ($N = 94$) scoring higher than participants from the West ($N = 59$;

Midwest: $p < 0.01$; South: $p = 0.04$). In addition, both region categories predicted

performance in Change Detection. East Coast participants ($N = 75$) took longer to respond

than West Coast ($N = 42$) participants ($p = 0.02$), and Northeastern participants ($N = 52$)

took longer to respond than participants who grew up in the West ($N = 52$; $p < 0.01$).

However, none of these relationships survived Bonferroni correction.

Basic demographic effects. We fit 192 exploratory regression models to see if basic demographic factors could predict task performance. The demographic factors we explored were age, gender identity, residential mobility, number of international experiences, maternal education level, and subjective socioeconomic status as measured by the MacArthur Ladder (Adler et al., 2000). 26 were statistically significant, but only one model survived Bonferroni correction. Change detection was predicted by age in the US sample, with older participants taking longer to respond than younger participants (adjusted $p <$ 0.01). Given some of the models could be considered as conceptual replications of previous work, we reported selected models with significant uncorrected results in Appendix D.

General Discussion

The world's cultures are strikingly different, and psychologists have long sought to measure and characterize this variation, with differences between Western and East Asian cultures as a case study of particular interest. These efforts have given rise to a rich literature documenting cultural differences in a wide range of psychological tasks. Across two experiments, we selected a collection of tasks that had previously been shown to yield differences between Western and East Asian samples and replicated them with two relatively large online samples of participants from the US and China. In this discussion, we first consider the limitations of our study since these contextualize the remainder of our conclusions. Next, we consider the interpretation of our results within individual tasks. We end the discussion with a summary of the key findings of this work.

General Limitations

As discussed above and in the introduction, we did not design our experiments to replicate prior work directly, and hence one important limitation of our work is simply that it cannot be used as a test of the reliability of prior findings. Instead, our measures provide estimates of US-China differences on a range of constructs, specifically for online convenience

samples. These estimates are likely biased downward – towards the null hypothesis of no difference between cultures – by several features of our experimental design.

Online experiments (especially grouped into a long battery as ours were) likely receive slightly less attention than in-person studies, though overall these effects have tended to be small in US samples (Buhrmester, Kwang, & Gosling, 2016). Contra this concern, however, participants did perform relatively accurately on those tasks that had correct answers (e.g., Raven's SPM, the Ebbinghaus Illusion), and in our exploratory analysis, we found relatively high reliabilities on all tasks. Further, our pre-registered exclusion criteria removed participants who performed poorly. Thus, we do not believe that participants were inattentive overall.

One might also be concerned about the reaction time measures (e.g. Ebbinghaus Illusion and Change Detection) collected through the online experiment. Due to variations in individual participants' hardware and internet conditions, the reaction times collected could potentially be more variable than those from in-person experiment. However, the validity of online reaction time measure has been evaluated and compared against in-person data across many different classic cognitive psychology tasks such as the Stroop task and the Flanker task. Across many tasks that require precise reaction time measures, online replications were qualitatively identical to the in-person version of the task (Crump, McDonnell, & Gureckis, 2013). Moreover, some works have also evaluated the accuracy and reliabiltiy of jsPsych, the JavaScript library that we used (Anwyl-Irvine, Dalmaijer, Hodges, & Evershed, 2021; Pinet et al., 2017). The consensus is that reaction time measures collected through jsPsych is reliable and accurate. Therefore, there is no reason to believe that the variability in our online reaction time measure deviated significantly from the in-person version of the reaction time task.

Another limitation of our estimates of US-China differences comes from variation in our sampling strategy between cultures. In Experiment 1, we used the same snowball

sampling procedure, but this procedure may have yielded different samples due to differences in social networks or norms about sharing study information across cultures. In Experiment 2, because the platform we used to recruit US participants (Prolific) was not accessible in China, we used a different platform to recruit Chinese participants (Naodao). Prolific and Naodao have different levels of popularity and different participant pools, resulting in some asymmetry between the US and Chinese samples. Despite these differences between samples both across and within experiments, we do not see indications that our estimates were dramatically biased by our sampling decisions. First, our results were largely comparable in the tasks that were included in both experiments (e.g. Picture Free Description; Raven's SPM; and Ambiguous cRMTS). Second, in our exploratory analyses we did not find strong associations between participant demographics and cross-cultural effects (with some small exceptions discussed in that section). Finally, we reran all of our preregistered analyses with an age-matched subset of U.S. participants in Experiment 2 and found our results were qualitatively identical.

Thus, while our samples are certainly not representative samples of US or Chinese national populations – indeed to our knowledge, nearly all work to date has used convenience samples of one type or another – they appear to yield stable cross-sample estimates that do not reflect large biases due to sampling strategy or demographics.

One of the main ways in which our samples may not have been representative is that they are likely to be more globalized than the population on average simply by being young (and thus less acculturated) and having access to a computer. Contra this concern, variation in local cultural identity did not strongly relate to variation in any of our tasks, but interestingly, we observed the strongest local identities (within our Chinese sample) among the youngest participants.

Last but not least, another difference between our experiments and previous work was the lack of an experimenter, and some of our tasks may be particularly sensitive to the

presence of an experimenter. In a web experiment, participants are often isolated in front of

their own computer. In contrast, in an in-person experiment, participants must interact with

and perform the task in front of experimenters who are often from the same social group.

Indeed, in the Uniqueness Preference pen choice task, cross-cultural differences are

dependent on the presence of an experimenter (Yamagishi, Hashimoto, & Schug, 2008). Our

null results, obtained in the absence of an experimenter, can be seen as a conceptual

replication of this work.

Task-specific Limitations

In addition to the general limitations discussed above, there are features of our

experimental adaptations that may have affected performance in specific tasks. In this

section, we highlight concerns about these issues and discuss their implications for

interpreting the results of these tasks. See Table 2 for a summary of this task-specific

discussion.

In the case of the Uniqueness Preference task, it is possible that adapting the task to

an online format in which resource scarcity was not strictly real and task choices had no

lasting effect (in the form of a new pen), may have trivialized the choice and undermined the

incentive for prosocial, harmonious behavior or expression. This possibility is consistent with

the chance responding we observed in both groups. Alternatively, our results could be seen

as a conceptual replication of Yamagishi et al. (2008), who argue that differences in this task

are moderated by the likelihood of evaluation, with no differences in pen choice observed in

the absence of an experimenter.

The ambiguous developmental tasks, Ambiguous cRMTS and Child Causal

Attribution, may have been too heavy-handed in their key manipulations; both were

designed to highlight ambiguity for young children, but it may be that their explicit cues and

repetitive instructions impressed this ambiguity too strongly for adult audiences, resulting in

757 the adults' near-chance responding – a reasonable response to such marked ambiguity.

758 Cultural differences in causal reasoning and attribution may only manifest when the task

759 design is age-appropriate. Consistent with this view, we did replicate previously attested

760 differences in the Adult Causal Attribution task in Experiment 2, and other recent work has

761 shown cross-cultural differences in causal attribution among 4- to 9-year-olds in Germany,

762 Japan, and Ecuador using a design similar to the Child Causal Attribution task (Jurkat, Iza

763 Simba, Hernández Chacón, Itakura, & Kärtner, 2022).

764   Last but not least, variation within the broad cultural constructs of East Asia and the

765 West could explain some of our findings, as a failure to extend previous work. Some of the

766 tasks we included originally compared participants from other parts of East Asia and the

767 West (e.g., Horizon Collage, Symbolic Self-Inflation, Change Detection; but c.f. Masuda,

768 Ishii, and Kimura (2016) for an alternative account of mixed findings in change detection

769 paradigms). For example, the Taxonomic-Thematic Similarity task replicated previously

770 attested cross-cultural differences between the US and China both here and in other work

771 (Le et al., 2021) but these differences failed to generalize to a US-Vietnam comparison,

772 despite the cultural, historical, and geographic similarities between China and Vietnam.

773 This variation suggests that similar psychological tendencies could be expressed differently

774 under distinct sociocultural contexts and traditions, even across regions and countries that

775 share many similarities. As another example, responding in the Horizon Collage could be

776 modulated by variation between countries: Chinese and Japanese aesthetic traditions differ,

777 so while Chinese and Japanese people may share a preference for highly contextualized

778 information, this preference may be typically expressed through distinct visual techniques.

779 **Conclusion**

780   We conducted two experiments to examine the robustness of several classic

781 experimental paradigms in cross-cultural psychology. Our results showed a heterogeneous

782 pattern of successes and failures: some tasks yielded robust cultural differences across both

experiments, while others showed no difference between cultures. We estimated the

reliability of the tasks to be moderate, with only minor variation in reliability across cultures.

We also explored the effects of a range of demographic variables, including explicit

identification with global identity, regional differences within cultures, and several

demographic characteristics. All of these had minimal relation to task performance.

Our goal here was not to perform direct replications that would shed light on the

replicability of specific findings. Instead, since our methods, administration medium, sample,

and analytic approach differed from the prior literature, our hope was to examine the

robustness of these paradigms as a method for measuring US-China differences in an online

context. Our work has several strengths relative to the prior literature, including larger

samples of participants from the US and China, two broad groups of tasks implemented

openly online (and reusable by future researchers), and a preregistered analysis plan that

allows for the unbiased estimation of cross-cultural effects. In sum, we hope that our work

here provides a foundation for future studies that seek to establish a robust and replicable

science of cross-cultural difference.

Table 2

Differences between our tasks, the original refernce tasks, and speculation about how these differences may have impacted our results.

Task Name	Difference between the current and original version	Speculative reasons
Ambiguous causal Relational Match-To-Sample (cRMTS)	• Age: The original experiment was conducted with young children; the current experiment was conducted with adults (but cf. Goddu, Sullivan, & Walker (2021) for non-chance adult performance in a very similar paradigm). • Test Format: The original experiment was conducted in person with physical stimuli and live experimenters; the current experiment was conducted through web-based interfaces with animation.	• The relation between objects might have been less salient when the stimuli were presented as schematic animation. • Adults may have been overall less engaged with the tasks and paid less attention to the causal properties of the object pairs.
Ebbinghaus Illusion	• Age: The original study was conducted with young children; the current experiment was conducted with adults. • Culture: The original experiment compared Japanese participants with Canadian participants; the current experiment compared Chinese participants with U.S. participants."	• Adults in both cultures reached ceiling performance. • U.S. and Chinese participants may differ in visual context sensitivity compared to Canadian and Japanese participants.

| Horizon Collage | • Age: The original experiment was conducted with young children; the current experiment was conducted with adults.
• Test Format: The original experiment was conducted in person with paper and collage stickers; the current experiment was conducted through web-based interfaces.
• Culture: The original experiment compared Japanese participants with Canadian participants; the current experiment compared Chinese participants with U.S. participants. | • The task might have been too trivial for adults to engage with properly.
• The saliency of horizon height is diminished by the drag-and-drop online interface. |
| Symbolic Self-Inflation (Family version and Friends version) | • Test Format: The original experiment was conducted in person with pen and paper; the current experiment was conducted through web-based interfaces.
• Test Prompt (Family version): The original experiment asked the participants to draw their close social network; the current experiment asked the participants to draw their family members or friends growing up. | • The online interface might have altered participants' drawing process, making it more difficult to implicitly represent the symbolic meaning of the circle size. |

Uniqueness Preference	• Test Format: The original experiment was conducted in person; the current experiment was conducted through web-based interfaces. • Stimulus: The original experiment gave away physical pens to keep; the current experiment asked participants to select virtual stickers. • Test Context: The original experiment prompted participants to make their pen selection after completing a questionnaire indicating their aesthetic preference for abstract art with unique or repeating shapes.	• The choice between virtual stickers is less meaningful than between real pens. • The presence of a live experimenter might increase the social pressure on participants, causing them to consider the cultural perception of their choice. • This richer context may have prompted more careful consideration of the key prompt.
Child Causal Attribution	• Age: The original experiment was conducted with young children; the current experiment was conducted with adults.	• Adults may have failed to engage deeply in causal reasoning because the story is too simplistic.
Change Detection	• Test Format: The original experiment was conducted in person; the current experiment was conducted through web-based interfaces.	• The in-lab setting might facilitate participants' performance by making them pay more attention to the computer screen.

Appendix A

Prospective Power analysis

We conducted two power analyses: a low assumption t-test power analysis and a high assumption linear mixed effects model power analysis. Under both power analysis frameworks, we showed that our sample sizes are well-powered to detect medium and larger effect sizes.

Low assumption t-test power analysis

In this framework, we assumed the cultural differences are evaluated with a simple t-test between two samples. We varied the hypothetical effect sizes of the cultural differences. This analysis was conducted using the `pwr` package (Champely et al., 2018).

High assumption mixed effects linear regression power analysis

Conducting prospective power analysis for mixed-effects linear regression requires more assumptions. Here we specify a simplified model to run the power simulation on. The model predicts a response with culture as the fixed effect, and subjects as the random intercepts. We assumed the fixed effect's intercept and slope as 0.1 and 0.5, respectively. We varied the effect sizes of the model by manipulating different residual standard deviation. We conducted this analysis in the `simr` package (Green & MacLeod, 2016).
Figure A1. Simulation of power under different sample sizes and effect sizes. The top panel is under t-test assumptions, and the bottom panel is under linear mixed effect model assumptions. X-axis represents the number of particints in each condition. Y-axis represents the estimated power based on the effect sizes and the sample sizes. The horizontal gray dotted line on each plot represents 80% power. The two vertical lines, green and purple, represents the minimum sample size and the maximum sample size in our study, respectively.

Appendix B

Additional Visualizations for Task Results

Free Description

One measure from the Picture Free Description task is the number of descriptive accounts directed at the focal objects versus the background objects. In Experiment 1, we found a main effect of culture, with U.S. participants providing more description overall. We also found an interaction effect between culture and description types, with U.S. participants providing more background descriptions than focal descriptions. This pattern was inconsistent with the results reported in Imada et al. (2013). However, we found a pattern consistent with the original findings in experiment 2: Chinese participants provided more descriptive accounts directed at the background objects than the focal objects relative to U.S. participants. We reported the descriptive and inferential statistics in the main text.

Figure B1. Results from the Picture Free Description task's descriptive accounts measures for experiment 1 and experiment 2 respectively. Each dot represents the number of descriptive accounts directed at either the focal object or the background object in each trial. Red indicates Chinese participants' responses, and blue indicates U.S. participants' responses. The black dots are the mean values for each group, with error bars showing 95% confidence intervals

Horizon Collage

In Horizon Collage task, we included two other measures in addition to the height of horizon: the number of stickers and the total area that the stickers covered. Here we included the visualization for the latter two measures. Unlike Senzaki et al. (2014), we did not see any cultural difference in either measure. We reported the descriptive and inferential statistics in the main text.

Figure B2. Results from the Horizon Collage task's sticker number and sticker covered area measures. Each dot represents one participant's response. Red indicates Chinese participants' responses, and blue indicates U.S. participants' responses. The black dots are the mean values for each group, with error bars showing 95% confidence intervals

Appendix C

Within-culture analysis on relationships between tasks.

Na et al. (2010) found neglible correlations among a battery of tasks that revealed cultural differences within each culture. We found similar patterns in our data. Here we report four correlation matrices: US participants' correlation matrix is on the left, and Chinese participants' on the right. Each cell has a number indicating the correlation between the task marked on the column head and the task marked on the row head (Experiment 1: CA = Child Causal Attribution; EBB: Ebbinghaus Illusion; FD = Free Description; HZ = Horizon Collage; RMTS = Ambiguous cRMTS; RV = Raven's Progressive Matrices; SSI = Symbolic Self-Inflation; UP = Uniqueness Preference; Experiment 2: RMTS = Ambiguous cRMTS; RV = Raven's Progressive Matrices; FD = Free Description; CD = Change Detection; SSI = Symbolic Self-Inflation; CA = Causal Attribution; TTS = Taxonomic-Thematic Similarity; SeI = Semantic Intuition).

Appendix D

Demographic variation in responses

In the exploratory analysis section, we explored how basic demographic variables could moderate the task performances within each culture. To do so, we fit an fixed effect model predicting each task's response in each culture, with each demographic variable as the predictor. We fit 192 exploratory regression models in total. 26 models were statistically significant, but only 1 survived Bonferroni correction. However, given that some of the demographic variables have been previously found to moderate task performance, we can treat this post-hoc exploratory analysis as a proxy for a conceptual replication. Therefore, we report selected uncorrected model results that are significant for key demographic variables in the tables below. These results should be interpreted with great cautions.

Residential Mobility

Higher residential mobility has been found to be related to individual's stronger emphasis on the independent self over the inter-dependent self (Ishii, Komiya, & Oishi, 2020; Oishi & Tsang, 2022). In our exploratory analysis's uncorrected models, residential mobility is a significant predictor to three task responses: U.S. participants' accuracy of Ebbinghaus Illusion task for U.S. participants, Chinese participants' proportion of first mention being focal objects in the Free Description task in Experiment 2, and U.S. participants' proportion of the taxonomic match selection in the Taxonomic-Thematic Similarity task. We reported the model results below.

Study	Culture	Task Name	Beta	SE	t	p
Experiment 1	US	Ebbinghaus Illusion	-0.01	0.01	-2.01	0.05
Experiment 2	CN	Free Description	0.03	0.01	2.45	0.02
Experiment 2	US	Taxonomic-Thematic Similarity	0.01	0.00	2.59	0.01

Socioeconomic Status

      MacArthur Ladder.   The MacAuthur ladder scale is a subjective measure of

socioeconomic status (Adler et al., 2000). This measurement has been found to show

moderate relationship with the objective socioeconomic measurements, and it has

even more robust relationship to individual's subjective well beings than objective

socioeconomic measurements (J. J. Tan, Kraus, Carpenter, & Adler, 2020). Past work

has used this measure to investigate the relationship between socioeconomic status

and individual's independent versus interdependent orientation (e.g., Miyamoto et al.,

2018). In our current study, this measure was a significant predictor for five different

tasks across two studies. In experiment 1, MacArthur Ladder scale response was

negatively correlated with the proportion of participants choosing the unique pen in

the U.S. participants. In experiment 2, this measure is negatively associated with the

relational match Chinese participants selected in the Causal RMTS task, the score

U.S. participants received in the Raven's Progressive Matrices, Chinese participants'

reaction time in the Change Detection task, and the proportion of taxonomic-match

Chinese participants selected in the Taxonomic-Thematic Similarity task. Theses

results were summarized in the table below.

Study	Culture	Task Name	Beta	SE	t	p
Experiment 1	US	Uniqueness Preference	-0.05	0.02	-2.36	0.02
Experiment 2	CN	Causal RMTS	-0.04	0.02	-2.05	0.04
Experiment 2	US	Raven's Progressive Matrices	-0.02	0.01	-2.14	0.03
Experiment 2	CN	Change Detection	-735.86	221.15	-3.33	< .001
Experiment 2	CN	Taxonomic-Thematic Similarity	-0.03	0.01	-2.05	0.04

      Maternal Education.   Maternal education is often regarded as a proxy for

socioeconomic status (Hauser, 1994; Hoff & Tian, 2005). In the exploratory analysis,

we first treated maternal education as a continuous variable. There was only one

significant result: Chinese participants reported having higher maternal education

made less situational attribution in the Causal Attribution task. Following common

practices in the literature, we also binned the maternal education into a binary

1087   variable – whether participants have received college education or not. The binary

1088   variable was not significantly related to any task performance.

Study	Culture	Task Name	Beta	SE	t	p
Experiment 1	CN	Causal Attribution	-0.08	0.04	-2.22	0.03

Appendix E

Examples of Tasks

Experiment 1

Ambiguous Relational Match-To-Sample (cRMTS). In the ambiguous cRMTS task (Carstensen et al., 2019, Experiment 3), participants were shown two pairs of objects, AB (A: blue square in the example setup shown in Figure E1; B: yellow circle) and AC (C: red triangle), activating a music machine during the training phase. In the test phase, they were given a forced choice between an object-based solution (a *same* pair of object A, i.e., a pair of blue squared in the example) and a relational solution (a *different* pair BC, i.e., yellow circle and red triangle in the example).
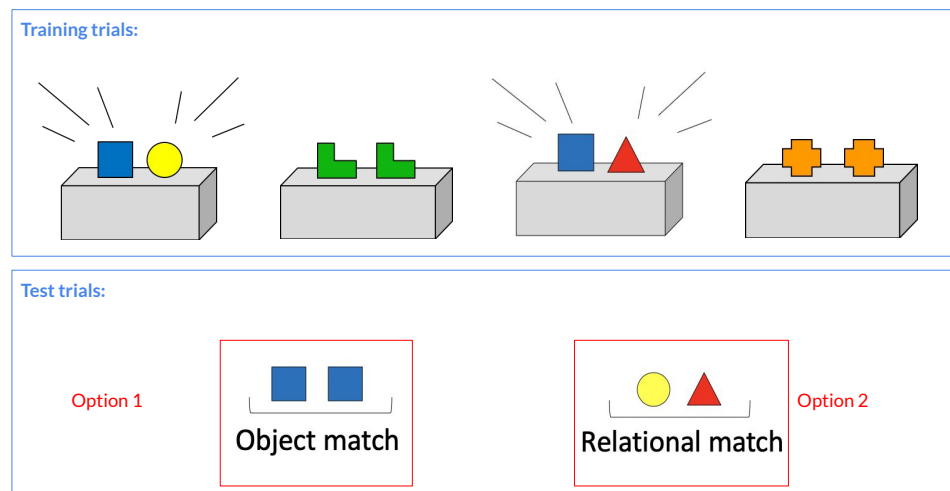

Figure E1. Ambiguous relational match-to-sample (cRMTS) task. Participants were given a forced choice between object-based solution (Option 1) and relational solution (Option 2) during the test phase.

Picture Free Description. In the picture free description task (Imada et al., 2013), Participants were shown a series of images with focal and background objects. For each image, they were asked to study it for 5 seconds, and then typed a description for it from memory.

... 5s ...

"Imagine you are talking to
someone who did not see this
picture. How would you tell them
what you saw? "

Figure E2. A practice trial in picture free description task. In this image, the cat is the focal object, and the rest are background objects.

**Ebbinghaus Illusion.** In the Ebbinghaus illusion task (Imada et al., 2013), participants were asked to indicate which of the two orange circles (see Figure E3) was larger. They completed the task in two blocks: (1) no context block (upper right panel), where the two orange circles appeared independently; (2) illusional context block (bottom right panel), where each of the two orange circles were flanked by a grid of 8 gray circles which are all smaller or larger than the center orange circle.

No
Context

"Which orange circle is the larger circle?"
Illusional Context

Figure E3. Ebbinghaus illusion task. Upper right panel: no context block. Bottom right panel: illusional context block.

1108 **Horizon Collage.** In the horizon collage task (Senzaki et al., 2014),

1109 participants were asked to create "a picture of the outside" by dragging-and-dropping

1110 sticker objects onto a rectangular "canvas." They were told to include a horizon line

1111 and could use any number of other stickers to create their image.

Figure E4. Horizon collage task. Participants created an image of the outside by dragging-and-dropping sticker objects onto a rectangular "canvas."

1112 **Symbolic Self-Inflation (Family).** In the adapted symbolic self-inflation

1113 task (Kitayama et al., 2009), we asked participants to draw themselves and their

1114 family members as circles by clicking-and-dragging their mouse on a rectangular
1115 "canvas."

Figure E5. Symbolic self-inflation task, family version. In this example, three circles were drawn representing the participant, their mother, and their father, respectively.

1116   **Uniqueness Preference.** In this adapted version of the uniqueness

1117 preference task (Kim & Markus, 1999), participants were asked to select one of the

1118 five dinosaur "stickers" that were identical except for color (four blue and one yellow).

"You can pick only one sticker. Which one do you want to pick?"

Figure E6. Uniqueness preference task. Participants were asked to select one of the five dinosaur "stickers."

1119   **Child Causal Attribution.** In the child causal attribution task (Seiver et

1120 al., 2013), participants watched a series of four short, animated vignettes in which

1121   two children both played in a pool and neither child played on a bicycle. They were

1122   then asked to explain in text why each child did not play on the bicycle.

Figure E7. Child causal attribution task. Participants were asked to explain why each child did not play on the bicycle

1123   **Raven's Standard Progressive Matrices.** In Raven's standard

1124   progressive matrices task, participants were asked to select from a series of given

1125   options one that best completed the patterns demonstrated in the prompts.

Figure E8. Raven's standard progressive matrices task. Participants were asked to select one option that best completed the patterns demonstrated in the prompts (upper panel).

Experiment 2

In Experiment 2, the following tasks followed the same procedures as in

Experiment 1: ambiguous relational match-to-sample (ambiguous cRMTS), picture

free description, and Raven's progressive matrices. The symbolic self-inflation task

also followed similar procedures as in Experiment 1, except that participants were

told to draw themselves and their *friends* into circles this time, as opposed to drawing

draw themselves and their *family members* into circles in Experiment 1. We show

examples for the remaining four tasks in Experiment 2 below.

Adult Causal Attribution. In the adult version causal attribution task

(Morris & Peng, 1994), participants were randomly assigned to read one of two crime

stories (Royal Oak shooting or Iowa shooting). They were then asked to write a short

explanation for the murderer's behaviors and rate a list of statements about the

causes of the murder (attributing to personal or situational factors) on a 7-point

Likert scale.

"In this portion of the study, we will ask for your opinion about homicide.
"Social scientists cannot, of course, do experiments to investigate what
causes someone to engage in mass murder. Therefore, we must search for
clues about possible causes by surveying people who share some
experiences of the persons involved--i.e., because they have lived in the
same region, at the same point in history (these homicides occurred in the
1990s), or because they are employed in the same line of work."

Royal Oak
Post Office Story

Iowa Story

Survey on why
(personal attribution & situational attribution)

Figure E9. Adult causal attribution task. Participants were randomly assiged to read one of two crime stories (Royal Oak shooting or Iowa shooting) and make attributions for the murder.

Change Detection. In each trial of the change detection task (Masuda & Nisbett, 2006), a pair of images would alternate on the screen, each presented for 560ms with a blank screen in between images for 80ms. The two pictures were almost identical with subtle differences, either in the focal object (e.g., a tractor with or without a wheel, as shown in the left panel of Figure E10) or the background (e.g., a scaffold in the distance with varying size, as shown in the right panel of Figure E10). Participants were instructed to press a key when they spotted the difference, and then describe the difference in a text box. If they did not detect a difference within 60 seconds, the trial timed out.
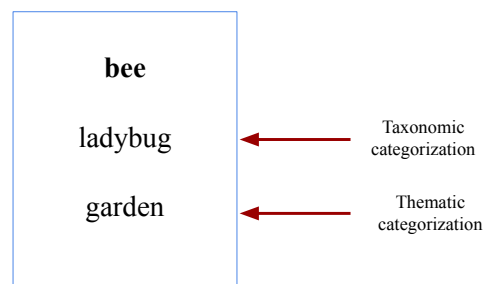

Change in <u>focal</u> objects   Change in <u>background</u> objects

Figure E10. Change detection task. Participants were instructed to detect the difference in each pair of images as quickly as they could. Left panel: change happened in a focal object. Right panel: change happened in the background.

Taxonomic-Thematic Similarity. In the taxonomic-thematic similarity task (Ji et al., 2004; Le et al., 2021), participants were presented with triads containing a cue word and two match options. In each test triad (as shown in Figure E11), one option was a taxonomic match (e.g., ladybug and bee are both insects) and the other a thematic match (e.g., bees usually appear in gardens). In each filler triads, the cue item and the options were broadly similar, thematically and taxonomically, making for a more ambiguous decision (e.g., monkey: elephant, tiger).

1156   Participants completed a two-alternative forced choice task in which they chose one

1157   match for each cue item.

In this game, you will see an item in bold, and two choices below it,
like this:

bee

ladybug   ⟵   Taxonomic
                       categorization

garden   ⟵   Thematic
                       categorization

Choose the option that is most closely related to the bolded item.

Figure E11. Taxonomic-thematic similarity task. Participants completed a two-alternative forced choice task in which they chose one match for each cue item.

1158   **Semantic Intuition.** In the semantic intuition task (Li et al., 2018),

1159   participants read five stories and judged the correctness of statements referring to a

1160   character after each story. The correctness judgement reflected their semantic

1161   intuition of either the descriptivist view (i.e., determine the referent of a name based

1162   on the description of the speaker) or the causal-historical view (i.e., determine the

1163   referent based on the original usage).

Super Dog Race
Long ago, there was a race called the Super Dog Race. Max, Pickles and Blaze participated in the race. Max crossed the finish line first, winning the race, but he got too excited and ran all the way to the North Pole. Pickles crossed the finish line second. He stopped and watched Max run away. The race announcer mistakenly thought that Pickles won the race. He told every newspaper in the world that Pickles won. He also told them that another dog, Blaze, ran very fast despite his short legs. Since then, everyone learned that Pickles won the race. They don't know anything else about Pickles.
Tom and Emily learned at school that Pickles won the Super Dog Race. This is the only thing they know about the dog race and Pickles. They don't know anything about Max. That night, their dad asked: Do you know who won the Super Dog Race?
Emily said: Pickles was the dog that won the Super Dog Race.

True: Descriptivist view
(Get reference from the definite description in her head)

False: Causal historical view
(Get reference based on causal-historical chain)

Figure E12. Semantic intuition task. In this specific example, judging the statement as "true" indicates a descriptivist view, and judging it as "false" indicates a causal-historical view.
